Clinical History

A 53-year-old woman with nephrotic syndrome under investigation is submitted to an ultrasound guided right kidney biopsy. There were no immediate complications reported. Approximately 24h after the procedure the patient complains of right lumbar pain without haematuria and a decrease in the haematocrit and haemoglobin levels is noticed.

Imaging Findings

An ultrasound study (Fig. 1) was the first examination to be carried out showing a heterogeneous liquid collection in the right perirenal space, postero-lateral to the kidney, measuring 9 cm in diameter, raising the possibility of a post biopsy haematoma given the clinical context.

It was followed by a CE-CT (Fig. 2) revealing two large haematomas, one in the right lateral abdominal wall and another in the right perirenal space. Active contrast extravasation could be
identified in both haematomas suggesting active haemorrhage. The patient was immediately taken to the angiography room and active haemorrhage from a right lumbar artery and from a distal interlobular branch of the lower division of the right renal artery were documented (Fig. 3, 5a), followed by successful embolisation. The lumbar artery was embolised using two 3 x 30 mm (diameter x length) coils and the renal arterial branch using 500-700 µm microspheres (Fig. 4ab, 5b).

Discussion

Renal haematomas are the most prevalent complication after percutaneous kidney biopsies but fortunately most of the times are self-limited situations without the need for active intervention [1]. Other complications like clinically significant arteriovenous fistula, infections or pneumothorax are considerably less frequent and life threatening complications are exquisitely rare being less than 0.1% [2]. These figures have improved much in recent years mainly due to the widespread use of ultrasound guidance and automated-gun biopsy devices [3].

One should be especially cautious with patients on anticoagulants or antiplatelet agents in spite of the lower risk reported in the literature for this last group. Extra care should be taken for patients with known haemorrhagic dyscrasias which have a very high risk of complicated bleeding after the procedure and should therefore be managed accordingly [4].

Persistent abdominal or lumbar pain, gross haematuria, new onset of oliguria, tachycardia and hypotension are the clinical indicators of major haemorrhage after a renal biopsy. At the slightest suspicion a kidney ultrasound can exclude the presence of a perirenal or subcapsular haematoma. The CT can help us characterise and precisely locate any ultrasound finding. With the use of contrast enhancement, active haemorrhagic leaks can be documented allowing the physician to decide whether a more aggressive approach is needed [5, 6].
We should be aware of false negative CT studies with slow bleeding below 0.5ml/min [7].

The definitive diagnosis is made by selective renal arteriography. A radiological interventional approach for acute bleeding complications after a percutaneous renal biopsy is currently, where available, the preferred choice, sparing patients nephrectomy. If not available, surgery will be the only option and nephrectomy inevitably necessary, partial or total, depending on the location of the bleeding artery [5, 6, 7]. The procedure can be extremely effective and even surprisingly simple in experienced hands. The Seldinger technique is used to catheterize the femoral artery, then a guide wire is passed into the renal artery and superselective catheterization of the most distal bleeding vessel is attempted. Next, transcatheter embolisation is performed and the immediate control of the bleeding is usually achieved. Metallic microcoils and acrylic microspheres are the most often used embolisation agents [8]. After a successful procedure a wedge-shaped infarct area can be observed with CE-CT and angiographically (Fig. 6).

In this case the percutaneous approach proved to be the best choice. The patient rapidly recovered. An abdominal CE-CT was repeated one week after the intervention and reduction of the haematomas without active bleeding was already evident.
Final Diagnosis

Post renal biopsy active haemorrhage from renal and lumbar artery

Differential Diagnosis List

Post biopsy haematoma without active haemorrhage, Post biopsy arterio-venous fistula, Perirenal abscess

Figures

Figure 1 Renal ultrasound

Heterogeneous liquid collection in the right flank suggestive of a post-biopsy haematoma.

Area of Interest: Kidney;
Imaging Technique: Ultrasound;
Procedure: Diagnostic procedure;
Special Focus: Haemorrhage;

Figure 2 Abdominal CE-CT
Axial arterial acquisition. Two haematomas are seen in the right postero-lateral abdominal wall and in the perirenal space pushing the kidney anterior and medially. In both, a linear image of contrast extravasation is clearly identified.

Portal phase CE acquisition showing that the contrast leakage increases due to active haemorrhage.
In this CE coronal reconstruction the active haemorrhagic leak can be seen near the lower pole of the right kidney corresponding to the biopsy needle insertion point.

Area of Interest: Kidney;
Imaging Technique: CT;
Procedure: Diagnostic procedure;
Special Focus: Haemorrhage;

Sagittal reconstruction of the same aspects in 2b and 2c. Haemorrhagic leak of the posterior lower pole of the right kidney.
In this further CE coronal reconstruction a second active haemorrhagic leak can be seen adjacent to the postero-lateral right abdominal wall, just above the iliac crest.
Sagittal reconstruction of the same aspects in 2b and 2e. Haemorrhagic leak of the postero-lateral abdominal wall.

Area of Interest: Kidney;  
Imaging Technique: CT;  
Procedure: Diagnostic procedure;  
Special Focus: Haemorrhage;

Figure 3 Angiography

Right kidney renogram. Regular opacification of the kidney with contrast leaking to the perirenal space.
The actively bleeding distal intralobular branch of the renal artery was selectively catheterised with a microcatheter and embolised using microspheres.

After the procedure the haemorrhage was successfully stopped. The embolised segment in the lower third of the kidney can be identified as a non-perfused peripheral wedge-shaped region.

**Figure 5 Angiography**

The lumbar artery responsible for the lateral abdominal haematoma was also found and selectively catheterised. The active haemorrhage was documented.
Embolisation of the bleeding lumbar artery with two coils stopped the haemorrhage. Notice that pooled contrast outside the artery persists despite the successful placement of the coils but does not increase with additional contrast injection.

Area of Interest: Interventional vascular; Kidney;
Imaging Technique: Catheter arteriography;
Procedure: Embolisation;
Special Focus: Haemorrhage;

Figure 6 Abdominal CE-CT - 1 week after the embolisation

Both haematomas have reduced in size and contrast extravasation is no longer present. In the right kidney a peripheral postero-lateral cortical wedge-shaped non-enhancing area corresponding to the post-embolisation infarct can be observed.
Area of Interest: Kidney;  
Imaging Technique: Ultrasound;  
Procedure: Diagnostic procedure;  
Special Focus: Haemorrhage;

MeSH

Kidney [A05.810.453]
Body organ that filters blood for the secretion of URINE and that regulates ion concentrations.

Biopsy [E01.370.388.100]
Removal and pathologic examination of specimens in the form of small pieces of tissue from the living body.
